# Chapter 1

## Introduction

$\mu$ ARM is an emulator program that implements a complete system with an emulated version of the ARM7TDMI processor as its core component. The processor's specifications have been respected, so instruction set, exception handling and processor structure are the same as any real processor of the same family. Since ARM7TDMI architecture does not detail a device interface and the memory management scheme is a bit too complex, these two components are based on  $\mu$ MPS2 architecture, which in turn takes inspiration from commonly known architectures.

In a more schematic fashion,  $\mu$ ARM is composed of:

- An ARM7TDMI processor.
- A system coprocessor, *CP15*, incorporated into the processor.
- Bootstrap and execution ROM.
- RAM memory little-endian subsystem with optional virtual address translation mechanisms based on Translation Lookaside Buffer.
- Peripheral devices: up to eight instances for each of five device classes. The five device classes are disks, tape devices, printers, terminals, and network interface devices.
- A system bus connecting all the system components.

This document will describe the main aspects of the emulated system, taking into exam each of its components and describing their interactions, further details regarding the processor can be found in the *ARM7TDMI Datasheet* and the *ARM7TDMI Technical Reference Manual*.

Notational conventions:

- Registers and storage units are **bold**-marked.

- Fields are *italicized*.
- Instructions are CAPITALIZED.
- Field  $F$  of register  $\mathbf{R}$  is denoted  $\mathbf{R}.F$ .
- Bits of storage units are numbered right-to-left, starting with 0.
- The  $i$ -th bit of a storage unit named  $N$  is denoted  $N[i]$ .
- Memory addresses and operation codes are given in hexadecimal and displayed in big-endian format.
- All diagrams illustrating memory are going from low addresses to high addresses using a left to right, bottom to top orientation.

# Chapter 2

## Processor

The  $\mu$ ARM machine runs on an emulated ARM7TDMI processor, which implements both ARM and Thumb instruction sets, is able to perform each operation listed in *ARM7TDMI Data Sheet* (a brief summary is shown below) and to accept painlessly binary programs compiled with the Gnu C Compiler for ARM7 architecture.

### 2.1 Operating modes and Processor registers

The processor can work in seven different modes:

- User mode (usr) - regular user process execution
- System mode (sys) - typical privileged mode execution (e.g. kernel code execution)
- Supervisor (svc) - protected mode kernel execution
- Fast Interrupt (fiq) - protected mode for fast interrupt handling
- Interrupt (irq) - protected mode for regular interrupt handling
- Abort (abt) - protected mode for data/instruction abort exception handling
- Undefined (und) - protected mode for undefined instruction exception handling

In each mode the processor can access a limited portion of all its registers, varying from 16 registers in User/System modes to 17 registers in each protected mode in ARM state, plus the Current Program Status Register (**CPSR**), which is shared by all modes. Only protected modes have the 17th register, which automatically stores the previous value of the **CPSR** when raising an exception.

The first 8 registers, in addition to the Program Counter (**R15**) are common to each "window" of visible registers, each protected mode has its dedicated Stack Pointer

and Link Return registers and Fast Interrupt mode has all the last 7 registers uniquely banked, to allow for a fast context switch, while System and User mode share the full set of 16 general purpose registers.

ARM State General Registers					
<i>User / System</i>	<i>FIQ</i>	<i>Svc</i>	<i>Abort</i>	<i>IRQ</i>	<i>Undef</i>
R0	R0	R0	R0	R0	R0
R1	R1	R1	R1	R1	R1
R2	R2	R2	R2	R2	R2
R3	R3	R3	R3	R3	R3
R4	R4	R4	R4	R4	R4
R5	R5	R5	R5	R5	R5
R6	R6	R6	R6	R6	R6
R7	R7	R7	R7	R7	R7
R8	R8_fiq	R8	R8	R8	R8
R9	R9_fiq	R9	R9	R9	R9
R10	R10_fiq	R10	R10	R10	R10
R11	R11_fiq	R11	R11	R11	R11
R12	R12_fiq	R12	R12	R12	R12
R13	R13_fiq	R13_svc	R13_abt	R13_irq	R13_und
R14	R14_fiq	R14_svc	R14_abt	R14_irq	R14_und
R15 (pc)	R15 (pc)	R15 (pc)	R15 (pc)	R15 (pc)	R15 (pc)
CPSR	CPSR	CPSR	CPSR	CPSR	CPSR
	SPSR_fiq	SPSR_svc	SPSR_abt	SPSR_irq	SPSR_und
<div></div> = banked register					

Even if the global 16 registers are defined as general purpose registers, there are some conventions adopted by the compiler in their use. The following list shows the full set of processor register visible in each mode with their conventional abbreviations and extended meaning:

- **R0 (a1)** - first function argument / integer result
- **R1 (a2)** - second function argument
- **R2 (a3)** - third function argument
- **R3 (a4)** - fourth function argument

- **R4 (v1)** - register variable
- **R5 (v2)** - register variable
- **R6 (v3)** - register variable
- **R7 (v4)** - register variable
- **R8 (v5)** - register variable
- **R9 (v6/rfp)** - register variable / real frame pointer
- **R10 (sl)** - stack limit
- **R11 (fp)** - frame pointer / argument pointer
- **R12 (ip)** - instruction pointer / temporary workspace
- **R13 (sp)** - stack pointer
- **R14 (lr)** - link register
- **R15 (pc)** - program counter
- **CPSR** - current program status register
- **SPSR<sub>mode</sub>** - saved program status register

When the processor is in Thumb state the register window is reduced, showing 12 registers in User/System mode and 13 registers in protected modes, in addition to the Current Program Status Register, which is common to all modes.

Only the first 8 registers (**R0** → **R7**) are general purpose, the higher 3 are specialized registers that act as Stack Pointer, Link Return and Program Counter. Each protected mode has its own banked instance of Stack Pointer and Link Return in addition to Saved Program Status Register to allow for faster exception handling.

Thumb State General Registers					
<i>User / System</i>	<i>FIQ</i>	<i>Svc</i>	<i>Abort</i>	<i>IRQ</i>	<i>Undef</i>
R0	R0	R0	R0	R0	R0
R1	R1	R1	R1	R1	R1
R2	R2	R2	R2	R2	R2
R3	R3	R3	R3	R3	R3
R4	R4	R4	R4	R4	R4
R5	R5	R5	R5	R5	R5
R6	R6	R6	R6	R6	R6
R7	R7	R7	R7	R7	R7
SP	SP_fiq	SP_svc	SP_abt	SP_irq	SP_und
LR	LR_fiq	LR_svc	LR_abt	LR_irq	LR_und
R15	R15	R15	R15	R15	R15
CPSR	CPSR	CPSR	CPSR	CPSR	CPSR
	SPSR_fiq	SPSR_svc	SPSR_abt	SPSR_irq	SPSR_und
<div></div> = banked register					

## 2.2 System Coprocessor

CP15 gives access to a total of three 64-bit and three 32-bit registers which provide additional information and functionalities to regular processor operations:

### Register 0 (IDC) - ID Codes

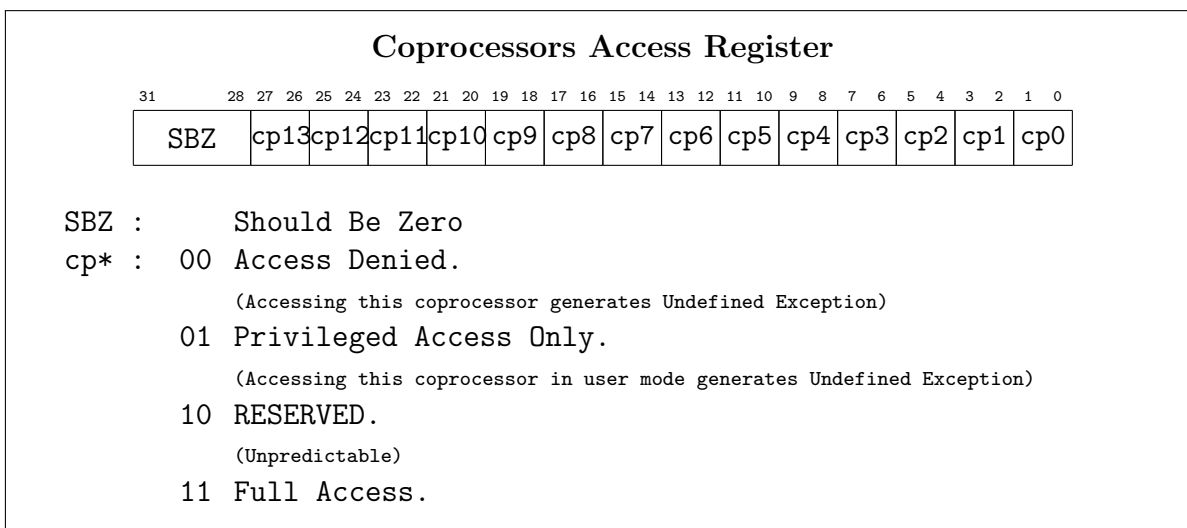

**R0** is a read-only 64-bit register that contains system implementation information such as *Processor ID* and *TLB type*, as required by ARM specifications.

### Register 1 (SCB) - System Control Bits

**R1.SCB** is the System Control Register, this register holds system-wide settings flags. See sec. 2.3.2 for further details.

## Register 1 (CCB) - Coprocessors Access Register

**R1.CCB** shows which coprocessors are available. Values can be written to this register to enable/disable available coprocessors a part from CP15.

## Register 2 - Page Table Entry

**R2** is a 64-bit register which contains the active Page Table Entry when MMU is enabled. Its structure is the same as the Page Table Entry described in sec. 4.2.

The lower 32 bits of this register are addressed as **CP15.R2.EntryLow** or just **EntryLow** and the higher 32 bits are addressed as **CP15.R2.EntryHi** or simply **EntryHi**.

## Register 8 - TLB Random

**R8** is a special read-only register used to index the TLB randomly (see sec. 4.2.3). This register is also addressed as **Random** or **TLBR**.

## Register 10 - TLB Index

**R10** is a special register used to index the TLB programmatically (see sec. 4.2.3). This register is also addressed as **Index** or **TLBI**.

## Register 15 (*Cause*) - Exception Cause

**R15.Cause** contains the last raised exception cause, it can be read or written by the processor.

A scheme of Memory Access exception cause codes is shown below:

Memory Error    = 1  
 Bus Error        = 2  
 Address Error   = 3  
 Segment Error   = 4  
 Page Error      = 5

## Register 15 (*IPC*) - Interrupt Cause

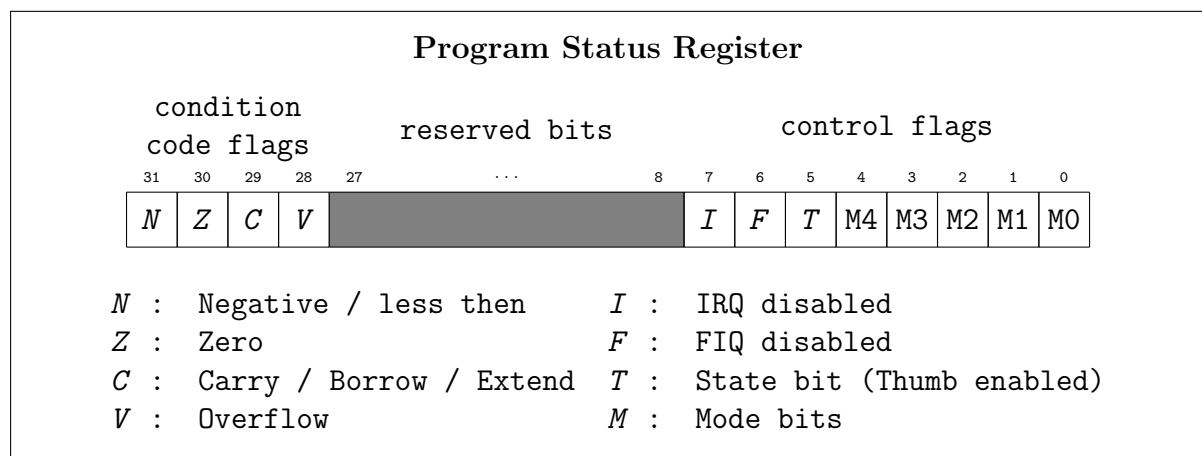

**R15.IPC** shows on which lines interrupts are pending, when interrupts have been handled (i.e. the interrupt request has been acknowledged, see sec. ??) the value of this register is updated.

## 2.3 Execution Control

The processor behavior can be set up by modifying the contents of two special registers: the Current Program Status Register (**CPSR**) and the System Control Register (**CP15.SCB**). Each of the two has a special structure and changes the way the system operates.

### 2.3.1 Program Status Register

The **CPSR** (as well as the **SPSR**, if the active mode has one) is always accessible in ARM state via the special instructions MSR (move register to PRS) and MRS (move PRS to register). This register shows arithmetical instructions' additional results (condition code flags), allows to toggle interrupts and switch states/modes. Its structure is shown below:

The first 5 bits of **CPSR** are used to set processor execution mode, the possible values are:

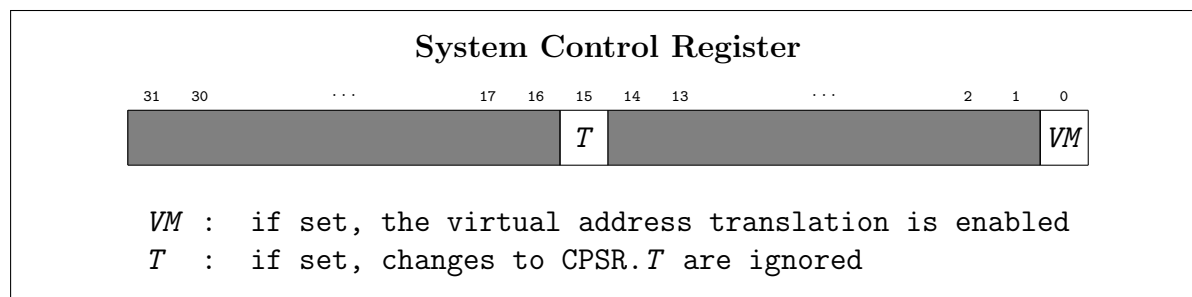

0x10	User Mode
0x11	Fast Interrupt Mode
0x12	Interrupt Mode
0x13	Supervisor Mode
0x17	Abort Mode
0x1B	Undefined Mode
0x1F	System Mode

User Mode is the only unprivileged mode, this means that if the processor is running in User Mode, it cannot access reserved memory regions (see System Bus chapter) and it cannot modify CPSR control bits.

System Mode is the execution mode reserved for regular Kernel code execution, all other modes are automatically activated when exceptions are raised (see sec. 2.5).

### 2.3.2 System Control Register

System Coprocessor (CP15) holds the System control register (**CP15.R1**), which controls Virtual Memory and Thumb availability (plus some other hardware specific settings that are not implemented in current release):

## 2.4 Processor States

The *T* flag of the Program Status Register shows the state of the processor, when the bit is clear the processor operates in ARM state, otherwise it works in Thumb state. To switch between the two states a Branch and Exchange (BX) instruction is required.

The first difference between the two states is the register set that is accessible (see sec. 2.1), the other main difference is the Instruction Set the processor is able to decode.

### 2.4.1 ARM ISA

The main Instruction Set is the ARM ISA, the processor starts execution in this state and is forced to ARM state when an exception is raised.

ARM instructions are 32 bits long and must be word-aligned. The table below shows a brief summary of the instruction set. (For a much detailed description of each instruction refer to *ARM7TMI Data Sheet* and *ARM7TMI Technical Reference Manual*)

ADC	add with carry	ADD	add
AND	logical AND	B	branch
BIC	bit clear	BL	branch with link
BX	branch and exchange	CDP	coprocessor data processing
CMN	compare negative	CMP	compare
EOR	logical exclusive OR	LDC	load coprocessor register from memory
LDM	load multiple registers from memory	LDR	load register from memory
LDRH	load halfword from memory	LDRSB	load signed byte from memory
LDRSH	load signed halfword from memory	MCR	move cpu register to coprocessor register
MLA	multiply accumulative	MLAL	multiply accumulative long
MOV	move register or constant	MRC	move coprocessor register to cpu register
MRS	move PRS status/flags to register	MSR	move register to PRS status/flags
MUL	multiply	MULL	multiply long
MVN	move negative register	ORR	logical OR
RSB	reverse subtract	RSC	reverse subtract with carry
SBC	subtract with carry	STC	store coprocessor register to memory
STM	store multiple	STR	store register to memory
STRH	store halfword	SUB	subtract
SWI	software interrupt	SWP	swap register with memory
TEQ	test bitwiser equality	TST	test bits
UND	undefined instruction		

### 2.4.2 Thumb ISA

Thumb instruction set is a simpler (smaller) instruction set composed of 16-bit, halfword aligned instructions, which offer less refined functionalities but less memory usage.

Thumb instructions can be seen as "shortcuts" to execute ARM code, as the performed operations are the same but this ISA offers less options for each instruction.

The following table summarizes Thumb instructions. (For a much detailed description of each instruction refer to *ARM7TMI Data Sheet* and *ARM7TMI Technical Reference Manual*)

ADC	add with carry	ADD	add
AND	logical AND	ASR	arithmetical shift right
B	unconditonal branch	B[cond]	conditioned branch
BIC	bit clear	BL	branch with link
BX	branch and exchange	CMN	compare negative
CMP	compare	EOR	logical exclusive OR
LDMIA	load multiple (increment after)	LDR	load word to register
LDRB	load byte to register	LDRH	load halfword to register
LDRSB	load signed byte to register	LDRSH	load signed halfword to register
LSL	logical shift left	LSR	logical shift right
MOV	move from register to register	MUL	multiply
MVN	move negative register	NEG	negate word
ORR	logical OR	POP	pop from stack
PUSH	push to stack	ROR	rotate right
SBC	subtract with carry	STMIA	store multiple (increment after)
STR	store register to memory	STRB	store byte to memory
STRH	store halfword to memory	SUB	subtract
SWI	software interrupt	TST	test bits

## 2.5 Exception Handling

When an exception is raised (e.g. a read instruction is performed on a forbidden bus address), the processor automatically begins a special routine to solve the problem. In addition to low level automatic exception handling facilities, the BIOS code implements a wrapper to simplify OS level handlers setup and functioning.

### 2.5.1 Hardware Level Exception Handling

There are seven different exceptions handled by the processor, each of those has a specific bus address to which the execution jumps on exception raising (see sec. 3.1.1).

When an exception is raised, the processor state is forced to ARM mode, the execution mode and the interrupt flags are set accordingly to the exception type, the **LR** register is filled with a return address and the **PC** is loaded with the correct address of the bus area

Exception Vector. If the Exception Vector has been correctly initialized, the instruction pointed to by the **PC** is a Branch instruction leading to some handler code.

Follows a brief description of the exceptions and the different return addresses.

### **Reset Exception**

This exception is automatically raised each time the machine is started.

This exception is handled in Supervisor mode with all interrupts disabled, Link Return and SPSR registers have unpredictable values and execution starts from bus address 0x0000.0000.

The first bus word, when the execution starts, is always filled with a fixed Branch instruction that makes the processor jump to the beginning of the bus-mapped ROM (address 0x0000.0300), where the BIOS is stored.

### **Undefined Instruction Exception**

If a Coprocessor instruction cannot be executed from any Coprocessor or if an UNDEFINED instruction is executed, this exception is raised.

Processor mode is set to Undefined, normal interrupts are disabled and Link Return register points to the instruction right after the one that caused the Undefined Exception.

### **Software Interrupt Exception**

This exception is caused by a SWI instruction and is meant to provide a neat way to implement System Calls.

When handling Software Interrupt Exceptions, the processor switches to Supervisor mode with normal interrupts disabled and the Link Return register points to the instruction after the SWI that caused the exception.

### **Data Abort Exception**

If the processor tries to access a memory address that is not valid or available, this exception is raised.

When handling Data Aborts, the processor switches to Abort mode with normal interrupts disabled and Link Return register is set to the address of the instruction that caused the Abort plus 8.

### **Prefetch Abort Exception**

If the processor tries to execute an instruction that generated a data abort while being fetched, this exception is raised.

When handling Prefetch Aborts, the processor enters Abort mode with normal interrupts disabled and Link Return register points to the address of the instruction after the one that caused the exception.

### **Interrupt Request Exception**

When a connected device requires the processor's attention, it fires an Interrupt Request.

When handling Interrupt Requests, the processor enters Interrupt mode with normal interrupts disabled and Link Return register is set to the address of the instruction that was not executed plus 4.

### **Fast Interrupt Request Exception**

Fast Interrupts have higher priority than normal Interrupts, system Interval Timer is connected to this line of interrupts.

The Interval Timer's value is decreased at each execution cycle, when an underflow occurs (i.e. its value changes from 0x0000.0000 to 0xFFFF.FFFF), a Fast Interrupt is requested.

When handling Fast Interrupt Requests, the processor enters Fast Interrupt mode with all interrupts disabled and Link Return register points to the address of the instruction that was not executed plus 4.

## **2.5.2 ROM Level Exception Handling**

During the bootstrap process, six of the seven Exception Vector registers must be initialized (the reset exception only occurs at system startup and the relative register has a fixed value). The BIOS code fills these registers with jump instruction opcodes pointing to its internal handler procedures.

The BIOS exception handlers provide a safe and automatic way to enter kernel level handlers by storing the processor state as it was before the exception was raised and loading the kernel handler's processor state from a known memory location inside the Kernel Reserved Frame (see sec. 3.1.7).

In addition to this general behavior, some handlers provide other functionalities as described below.

### **Undefined Instruction Handler**

An Undefined Instruction Exception needs no special treatment, its handler stores the old processor state into the PGMT Old Area and loads the processor state stored into the PGMT New Area.

## Software Interrupt Handler

Software interruptions recognized by the BIOS handler can be of two types: System Calls or Breakpoints, the foremost being interpreted as a request to the kernel, while the latter can also be a BIOS service request.

This handler is capable of recognizing BIOS service requests and serving them directly, if a System Call or an unrecognized Breakpoint is requested, the exception is handled with the default behavior, the old processor state is stored into the Syscall Old Area and the processor state stored into the Syscall New Area is loaded.

## Data Abort and Prefetch Abort Handler

If Virtual Memory is enabled (see sec. 4.2), both Data and Prefetch Aborts can be raised while accessing a memory frame whose VPN is not loaded into the TLB, event signaled by the memory subsystem through these two exceptions. If this is the case, the BIOS will automatically perform a TLB\_Refill cycle, searching the active Page Tables for the required entry; otherwise the exception is treated as a generic exception, storing the old processor state into TLB Old Area and then loading the processor state stored into the TLB New Area.

Since the two different exception types have different return address offsets (see sec. 2.5.1), this handler modifies the return address stored within the old processor state in order to be the correct address to jump to. This behavior is necessary, because discerning the exception type from kernel level handler could be quite difficult, or even impossible at times, without the knowledge of the hardware level exception, that is given from processor mode and **CPSR.R15.Cause** and could be lost during the pass-up.

## Interrupt and Fast Interrupt Handlers

Both these exceptions are treated as generic exceptions and the BIOS handlers will adopt the default behavior, storing the old processor state into the Interrupt Old Area and then loading the processor state stored into the Interrupt New Area.

# Chapter 3

## System Bus

The system bus connects each component in the system and lets processing units access physical memory and devices, as well as some special purpose registers.

The CPU and the System Coprocessor (CP15) can directly access the bus reading or writing values from or to specific addresses.

The lower addresses (below 0x0000.8000) are reserved for special uses and are accessible under certain conditions.

### 3.1 Reserved address space

The address region between 0x0000.0000 and 0x0000.8000 holds the fast exception vector, device access registers, system information registers, bootstrap ROM and the kernel reserved frame (i.e. the first RAM frame). Any access to this memory area in User mode is (should be) prohibited and treated by the system bus as errors.

### 3.1.3 Device Registers

Addresses from 0x0000.0040 to 0x0000.02C0 hold device registers. Each device type has its own communication protocol, as described in chapter 5.

### 3.1.4 System Information Registers

Six registers, from address 0x0000.02D0 to 0x0000.02E4, show system specific information:

System Information Registers	
Interval Timer	0x0000.02E4
Time of day (Low)	0x0000.02E0
Time of day (High)	0x0000.02DC
Device registers base addr.	0x0000.02D8
RAM top address	0x0000.02D4
RAM base address	0x0000.02D0

These registers are all read-only, except for the interval timer which is a special device register (see sec. 5.2.1), and are aimed to provide useful information to the operating system.

### 3.1.5 Bootstrap ROM

The bootstrap ROM is loaded starting from address 0x0000.0300, its maximum size is 109 KB. The content of the ROM is actually flashed at each reboot of the emulator copying each byte of the input image starting from the ROM base address, so the BIOS image does not need any special offset set by the linker.

See section 6.1 for further details regarding provided BIOS implementation.

### 3.1.6 Pending Interrupts Bitmap

All the devices of one class are connected to the same interrupt line, when a device needs to notify some activity to the processor it sends a message through its interrupt line. To identify which specific device is requesting an interruption, there are five registers from address 0x0000.6FE0 to 0x0000.6FF0 that hold a bitmap of interrupting devices per interrupt line.

For each word,  $i$  bit is set if  $i^{\text{th}}$  device on that line is requesting for interrupt.

This region is organized exactly as the Installed Device Table:

3.1.7 Kernel Reserved Frame

The first memory frame (0x0000.7000 → 0x0000.7FFC) is reserved for kernel use:

The Exception states vector is a memory area to which processor states are saved and loaded from when entering into/exiting from exception handlers code. The Segment table holds 128 elements describing the virtual address space, for each ASID (corresponding

to one entry in the segment table) there are three pointers to ASID's page tables (see sec. 4.2.2). When invoking ROM functions, the four words wide ROM stack (the last four words in the frame) is used as a memory stack and to pass parameters by the low level routines.

## Stored Processor States

Processor states are defined by library data structure *state\_t*, this structure is composed of 22 unsigned 32-bit integers representing processor registers' values and coprocessor's system control registers' values as well as saving time.

Its structure is shown below:

```
typedef struct {
    unsigned int a1;    //r0
    unsigned int a2;    //r1
    unsigned int a3;    //r2
    unsigned int a4;    //r3
    unsigned int v1;    //r4
    unsigned int v2;    //r5
    unsigned int v3;    //r6
    unsigned int v4;    //r7
    unsigned int v5;    //r8
    unsigned int v6;    //r9
    unsigned int s1;    //r10
    unsigned int fp;    //r11
    unsigned int ip;    //r12
    unsigned int sp;    //r13
    unsigned int lr;    //r14
    unsigned int pc;    //r15
    unsigned int cpsr;
    unsigned int CP15_Control;
    unsigned int CP15_EntryHi;
    unsigned int CP15_Cause;
    unsigned int TOD_Hi;
    unsigned int TOD_Low;
} state_t;
```

These structures take 88 bytes each. Given this value, the BIOS code will look for the Old/New entries at the following addresses:

### Exception States Vector

Syscall New	0x0000.73B8
Syscall Old	0x0000.7330
PGMT New	0x0000.72A8
PGMT Old	0x0000.7220
TLB New	0x0000.7198
TLB Old	0x0000.7110
Interrupt New	0x0000.7088
Interrupt Old	0x0000.7000

Each time an exception is risen, the BIOS handlers will store the processor state before the exception into the proper Old area, perform other tasks where required (see sec. 2.5.2) and eventually load the processor state stored in the corresponding New area.

The New areas must be filled with valid processor states pointing to kernel level exception handlers by kernel initialization stage.

## 3.2 Memory address space

The remaining addresses ( $0x0000.8000 \rightarrow \text{RAMTOP}$ ) are mapped to memory subsystem, this bus region can be directly accessed by the processor and the coprocessor, it is used to store the kernel execution code and data as well as any other program that has to be executed.

The memory is accessible in physical addressing mode or virtual addressing mode, access modes and memory structure are described in detail in chapter 4.

# Chapter 4

## Memory Interface

Memory system is controlled by Program Status Register (**CPSR**) and System Coprocessor's registers 1 and 2 (**CP15.R1** & **CPSR.R2**). It supports two operating modes:

- physical addressing mode,
- virtual addressing mode.

In addition to address translation modes, the portion of accessible memory is dictated by processor operating mode:

- User mode → User Space
- Privileged mode → All Memory

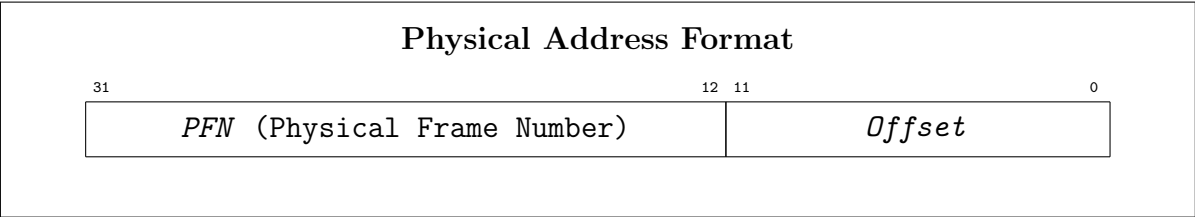

In each addressing mode these portions have a specific definition.

As stated in section 3.1, addresses below `0x0000.8000` are reserved for hardware/protected functions and belong to the reserved address space independently from the active addressing mode.

### 4.1 Physical addressing mode

This is the basic memory access scheme, when enabled, any memory access is directed to the physical address specified in the request, without any conversions. The machine begins execution with this mode active.

The physical address space is divided into equal sized frames of 4KB each. Hence a physical address has two components; a 20-bit Physical Frame Number or *PFN*, and a 12-bit *Offset* into the frame. Physical addresses have the following format:

All the available memory is directly accessible in Privileged mode and any address over 0x0000.8000 is directly accessible in User mode.

Trying to access an address below 0x0000.8000 while in User Mode will raise an **Address Error** exception.

The installed physical RAM starts at 0x0000.7000 and continues up to **RAMTOP**, this area will hold:

- The operating system code (text), global variables/structures (data), and stack(s).
- The user processes text, data and stacks.
- The Kernel Reserved Frame. As detailed in section 3.1.7, the BIOS code needs some writable storage to interact with the Kernel. The first 4KB (i.e. the first frame) of physical RAM are reserved for this purpose.

The first 7KB of the physical address space are reserved for Bus functions, as described in section 3.1. Any attempt to access an unidentified memory area will generate a **BUSERROR** exception.

## 4.2 Virtual addressing mode

When virtual memory is active, each address above 0x0000.8000 is treated as a logical address and translated to the corresponding physical address from the memory subsystem. Addresses below 0x0000.8000 are always treated as physical addresses, as they refer to a reserved address region (see sec. 3.1).

By setting *M* flag in System Coprocessor's register 1 (**CP15.R1.M**), you enable memory address translation.

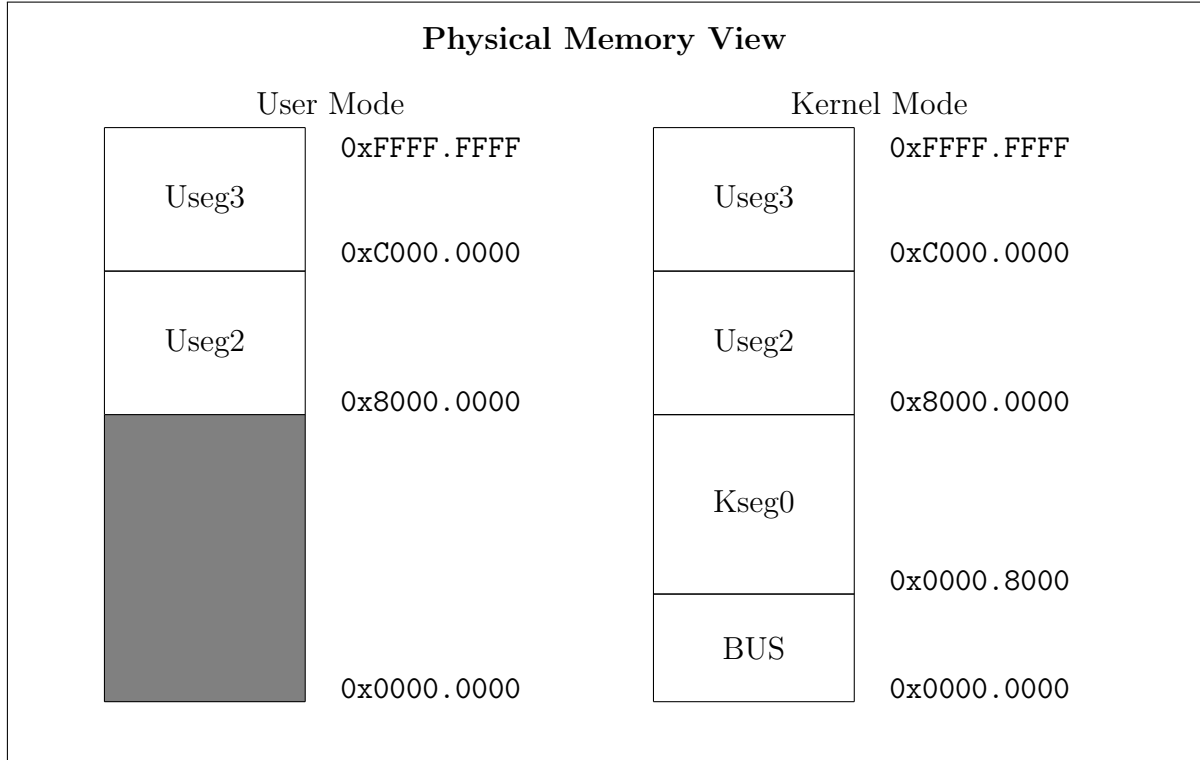

The first two bits of a virtual address are the Segment Number (*SEGNO*). Virtual pages are the same size as physical frames, the final 12-bits indicate an *Offset* into a memory frame. The remaining 18-bits indicate the Virtual Page Number or *VPN*. Virtual addresses have the following format:

The segment number is composed of two bits, the most important one differentiates kernel and user segments, the least important one is meaningful only in user segment and identifies private segment and global segment:

- Kseg0 (*SEGNO* 0 and 1) is the 2GB segment for the OS text, data, stacks, as well as the ROM code and device registers that sit at the beginning of this segment.
- Useg2 (*SEGNO* 2) is the 1GB virtual address space for the use of User mode processes as private memory region.
- Useg3 (*SEGNO* 3) is the 1GB virtual address space for the use of User mode processes as shared/global memory region.

In Privileged mode all logical memory is accessible, while in User mode only User Segments are accessible and any access to Kseg0 segment will generate an **Address Error** exception.

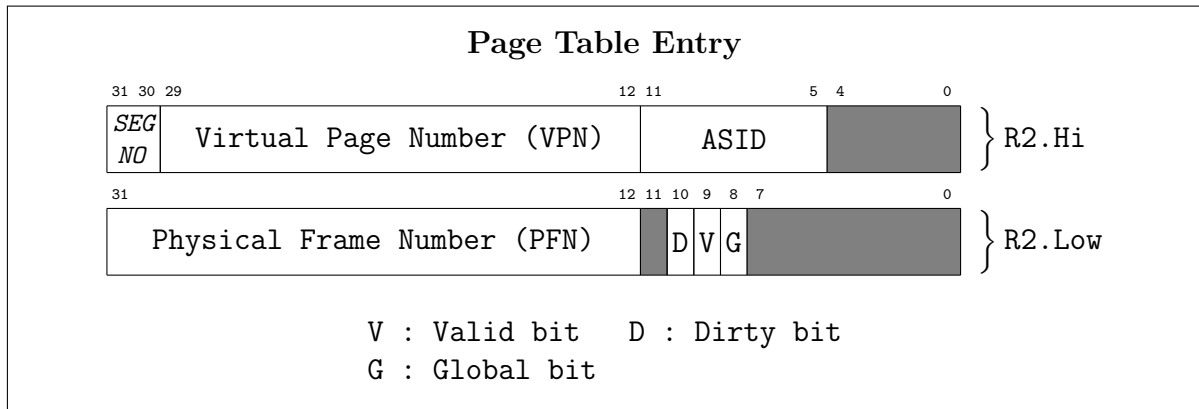

As part of its VM implementation,  $\mu$ ARM assigns to each process a 7-bit identifier; hence  $\mu$ ARM natively allows up to  $2^7 = 128$  concurrent processes. To reflect the fact that each of these processes will run in its own virtual address space, this identifier is called the Address Space Identifier (*ASID*). The current *ASID* is part of the processor state and is stored in **EntryHi.ASID** (**CP15.R2.EntryHi.ASID**).

When the MMU is enabled the user process *ASID* is stored in the **EntryHi** register along with the Virtual Page number (i.e. the 20 most significant bits of the logical address). The **EntryLow** register is filled with the Physical Frame Number from the relevant page table and is kept up to date after each modification of **CP15.R2.EntryHi** value.

#### 4.2.1 Page Table

The **CP15.R2** register is organized as a Page Table Entry (PTE):

The Hi half of each entry identifies the logical frame to which the entry refers and the *ASID* of the owning process. The Low half of each entry specifies the physical correspondig frame (if any) and contains 3 flags used for memory protection schemes:

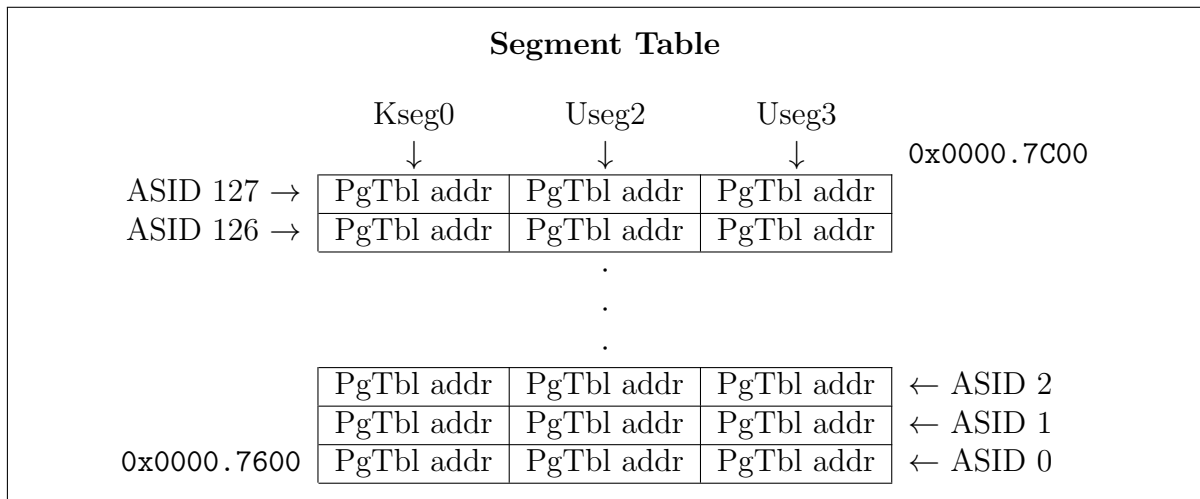

- **Dirty bit:** if the flag is clear, any write access to the physical frame locations will rise a **TLB-Modification** exception.
- **Valid bit:** if the flag is set the Page Table Entry is considered valid, otherwise a **TLB-Invalid** exception is raised. This flag should be set only when the *PFN* points to the actual memory frame.
- **Global bit:** if the flag is set, the Page Table Entry will match the corresponding *VPN* regardless of the *ASID*.

Page Table Entries are grouped together in Page Tables, each Page Table begins with a special word (PgTbl-Header) composed of the PgTbl Magic Number **0x2A** stored in the most significant 8 bits and the number of page table entries in the least significant 20 bits, as shown below.

## 4.2.2 Segment Table

The Segment Table specifies the physical addresses of the Page Tables describing the three Segments for each *ASID*, the general structure is shown below:

The segment table is automatically accessed from BIOS code when the Page Table Entry describing a needed memory frame is not present inside the TLB and needs to be retrieved (see sec. 4.2.3).

### 4.2.3 Translation Lookaside Buffer

$\mu$ ARM implements a Translation Lookaside Buffer (TLB) to translate virtual addresses to physical addresses, the buffer contains a specific amount of recently used PTEs and can use a variety of algorithms to select which entry to replace with a newly retrieved PTE (the BIOS handler implements a simple random selection). The number of available TLB slots is variable between 4 and 64 elements, it is configurable through the settings window of the emulator and needs a reset of the machine to effectively change.

Each time a memory access is requested, the memory subsystem checks if the requested Virtual Page has a corresponding PTE in the TLB for the current *ASID* or with the *G* flag set. If the necessary PTE is not present in the TLB, a **TLB-Miss** exception is raised and the BIOS reacts with a TLB Refill event, which is composed of the next steps:

1. Retrieve the PgTbl address from the Segment Table for the current ASID and required Segment.
2. Access the PgTbl and check if it is well-formed and well-located:
  - Address must be greater than 0x0000.8000,
  - Address must be word aligned,
  - PgTbl-Header must be valid (magic number is 0x2A),
  - PgTbl must not extend outside physical memory (e.g. [PgTbl addr + PgTbl size] < RAMTOP).

If one of these checks fails a **Bad-PgTbl** exception is raised.

3. Linearly search the PgTbl for matching Virtual Page with correct *ASID* or *G* flag set.
4. If a matching PTE has been found, write it back in a random slot of the TLB and resume execution from the same instruction that raised the **TLB-Miss** exception, else raise a **PTE-Miss** exception.

At this point, either there is a matching PTE, or an exception has been raised (either an **Address Error**, **Bad-PgTbl**, or **PTE-Miss** exception). If there is a matching TLB entry then the *V* and *D* control bits of the matching PTE are checked respectively. If no **TLB-Invalid** or **TLB-Modification** exception is raised, the physical address is constructed by concatenating the *Offset* from the virtual address to be translated to the *PFN* from the matching PTE.

## CP15 registers used in address translation

CP15 implements four registers used to support virtual address translation. The first two have already been described, they are **CP15.R1** and **CP15.R2**, used respectively to turn on or off address translation and to cache the active Page Table Entry.

The contents of the TLB can be modified by writing values into the **EntryHi** and **EntryLo** registers and issuing either the TLB-Write-Index (TLBWI) or TLB-Write-Random (TLBWR) CP15 instruction. Which slot in the TLB the entry is written into is determined by which instruction is used and the contents of either the **CP15.R8 (Random)** or **CP15.R10 (Index)** register. Both the **Random** and the **Index** registers have a 6-bit *TLB-Index* field which addresses one of the TLBSIZE slots in the TLB.

The **Index** register is a read/writable register. When a TLBWI instruction is executed, the contents of the **CP15.R2** register are written into the slot indicated by **Index.TLB-Index**.

The **Random** register is a read-only register used to index the TLB randomly; allowing for more effective TLB-refiling schemes. **Random.TLB-Index** is initialized to TLBSIZE-1 and is automatically decremented by one every processor cycle until it reaches 1 at which point it starts back again at TLBSIZE-1. This leaves one TLB safe entry (entry 0) which cannot be indexed by **Random**. When a TLBWR instruction is executed, the contents of the **CP15.R2** register are written into the slot indicated by **Random.TLB-Index**. ( $\mu$ ARMs TLB Refill algorithm uses TLBWR to populate the TLB.)

Three other useful CP15 instructions associated with the TLB are the TLB-Read (TLBR), TLB-Probe (TLBP), and the TLB-Clear (TLBCLR) commands.

- The TLBR command places the TLB entry indexed by **Index.TLB-Index** into the **CP15.R2** register. Note, that this instruction has the potentially dangerous affect of altering the value of **EntryHi.ASID**.
- The TLBP command initiates a TLB search for a matching entry in the TLB that

matches the current values in the **EntryHi** register. If a matching entry is found in the TLB the corresponding index value is loaded into **Index.TLB-Index** and the Probe bit (**Index.P**) is set to 0. If no match is found, **Index.P** is set to 1.

- The TLBCLR command zeros out the unsafe TLB entries; entries 1 through TLBSIZE-1. This command effectively invalidates the current contents of the TLB cache.

See Sections 6.2 for more details on the TLBWI, TLBWR, TLBR, TLBP, TLBCLR CP15 instructions and how to access the **CP15.R2** and **Index** registers.

# Chapter 5

## External Devices

[FIND AND REPLACE , MPS2]

MPS2 supports five different classes of external devices: disk, tape, network card, printer and terminal. Furthermore, MPS2 can support up to eight instances of each device type. Each single device is operated by a controller. Controllers exchange information with the processor via device registers; special memory locations.

A device register is a consecutive 4-word block of memory. By writing and reading specific fields in a given device register, the processor may both issue commands and test device status and responses. MPS2 implements the full-handshake interrupt-driven protocol. Specifically:

1. Communication with device  $i$  is initiated by the writing of a command code into device  $i$ 's device register.
2. Device  $i$ 's controller responds by both starting the indicated operation and setting a status field in  $i$ 's device register.
3. When the indicated operation completes, device  $i$ 's controller will again set some fields in  $i$ 's device register; including the status field. Furthermore, device  $i$ 's controller will generate an interrupt exception by asserting the appropriate interrupt line. The generated interrupt exception informs the processor that the requested operation has concluded and that the device requires its attention.
4. The interrupt is acknowledged by writing the acknowledge command code in device  $i$ 's device register.
5. Device  $i$ 's controller will de-assert the interrupt line and the protocol can restart. For performance purposes, writing a new command after the interrupt is generated will both acknowledge the interrupt and start a new operation immediately.

The device registers are located in low-memory starting at 0x0000.0040. As explained in section 4.2, regardless of **CP15.R1.M**, all addresses between 0x0000.0200 and **DEVTOP** are interpreted as physical addresses. Furthermore, the device registers can only be accessed when the processor is executing in privileged mode.

The following table details the correspondence between device class/type and interrupt line.

Interrupt Line #	Device Class
0	Inter-processor interrupts
1	Processor Local Timer
2	Bus (Interval Timer)
3	Disk Devices
4	Tape Devices
5	Network (Ethernet) Devices
6	Printer Devices
7	Terminal Devices

Some important issues relating to device management:

- Since there are multiple interrupt lines, and multiple devices attached to the same interrupt line, at any point in time there may be multiple interrupts pending simultaneously; both across interrupt lines and on the same interrupt line.
- The lower the interrupt line number, the higher the priority of the interrupt. Note how fast/critical devices (e.g. disk devices) are attached to a high priority interrupt line while slow devices are attached to the low priority interrupt lines.
- Interrupt lines 37 are used for external devices. Interrupt lines 0-2 are for internally generated interrupts. Lines 0-1 are present for future multiprocessor support, but currently unused.
- Disk and tape devices support Direct Memory Access (DMA); that is through cooperation with the bus, these devices are able to transfer whole blocks of data to/from memory from/to the device. Data blocks must be both wordaligned and of multiple-word in size. MPS2 supports any number of concurrent DMA operations; each on a different device. Care must be taken to prevent simultaneous DMA operations on the same chunk of memory.
- After an operation has begun on a device, its device register freezes - becomes read-only - and will not accept any other commands until the operation completes.
- Any device register for an uninstalled device is frozen - set to zero - and subsequent writes to the device register have no effect.

- Device registers use only physical addresses; this includes addresses used in DMA operations.
- Each external device in MPS2 is identified by the interrupt line it is attached to and its device number; an integer in  $[0..7]$ . MPS2 limits the number of devices per interrupt line to eight.
- For performance reasons, devices in the same class are, by default, attached to the same interrupt line.

## 5.1 Device Registers

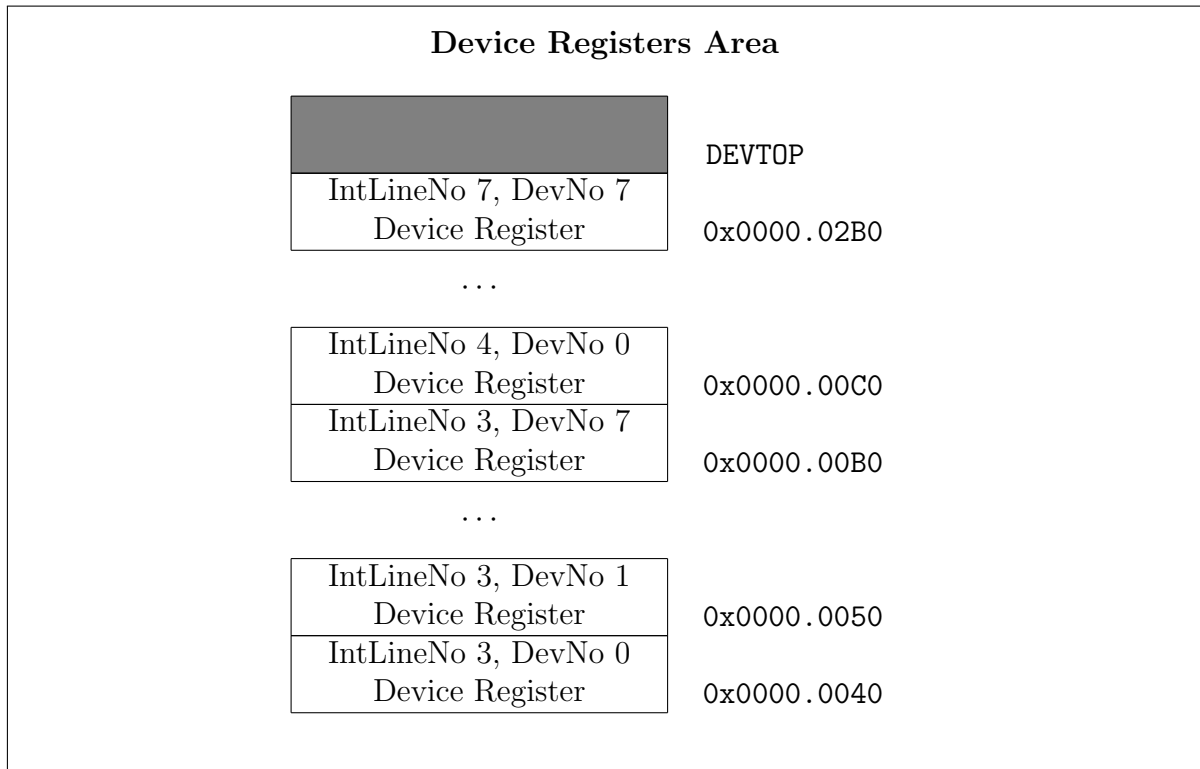

All external devices share the same device register structure.

While each device class has a specific use and format for these fields, all device classes, except terminal devices, use:

- **COMMAND** to allow commands to be issued to the device controller.
- **STATUS** for the device controller to communicate the device status to the processor.
- **DATA0** & **DATA1** to pass additional parameters to the device controller or the passing of data from the device controller.

Field #	Address	Field Name
0	(base) + 0x0	<b>STATUS</b>
1	(base) + 0x4	<b>COMMAND</b>
2	(base) + 0x8	<b>DATA0</b>
3	(base) + 0xC	<b>DATA1</b>

All 40 device registers in MPS2 are located in low memory starting at 0x0000.0040.

Given an interrupt line (IntLineNo) and a device number (DevNo) one can compute the starting address of the devices device register:

$$\text{devAddrBase} = 0x0000.0040 + ((\text{IntlineNo} - 3) * 0x80) + (\text{DevNo} * 0x10)$$

## 5.2 The Bus Device and Interval Timer

The bus acts as the interface between the processor and the RAM, ROM, and all the external devices. In particular the bus performs the following tasks:

1. Management of the time of Day (TOD) clock and Interval Timer.
2. Arbitration among the interrupt lines, the devices attached to each interrupt line and the device registers.
3. Repository of basic system information.

### 5.2.1 Interval Timer

A read/writable unsigned word that is decremented by one every processor cycle and is set by MPS2 circuitry to 0xFFFF.FFFF at system boot/reset time. The Interval Timer

will generate an interrupt on interrupt line 2 whenever it makes the `0x0000.0000`  $\rightarrow$  `0xFFFF.FFFF` transition. This is the only device attached to interrupt line 2, hence any interrupt on this line may be assumed to be associated with the Interval Timer. Interval Timer interrupts are acknowledged by writing a new value into the Interval Timer register.

The Interval Timer device register is located at `0x0000.02E4` (see sec. 3.1.4).

## 5.3 Disk Devices

MPS2 supports up to eight DMA supporting read/writable hard disk drive devices. All MPS2 disk drives have a blocksize equal to the MPS2 framesize of 4KB. Each installed disk drives device register **DATA1** field is read-only and describes the physical characteristics of the devices geometry.

MPS2 disk drives can have up to 65536 cylinders/track, addressed  $[0..(MAXCYL-1)]$ ; 256 heads (or track surfaces), addressed  $[0..(MAXHEAD-1)]$ ; and 256 sectors/track, addressed  $[0..(MAXSECT-1)]$ . Each 4KB physical disk block (or sector) can be addressed by specifying its coordinates: (cyl, head, sect).

A disk drives device register **STATUS** field is read-only and will contain one of the following status codes:

Code	Status	Possible Reason for Code
0	Device Not Installed	Device not installed
1	Device Ready	Device waiting for a command
2	Illegal Operation Code Error	Device presented unknown command
3	Device Busy	Device executing a command
4	Seek Error	Illegal parameter/hardware failure
5	Read Error	Illegal parameter/hardware failure
6	Write Error	Illegal parameter/hardware failure
7	DMA Transfer Error	Illegal physical address/hardware failure

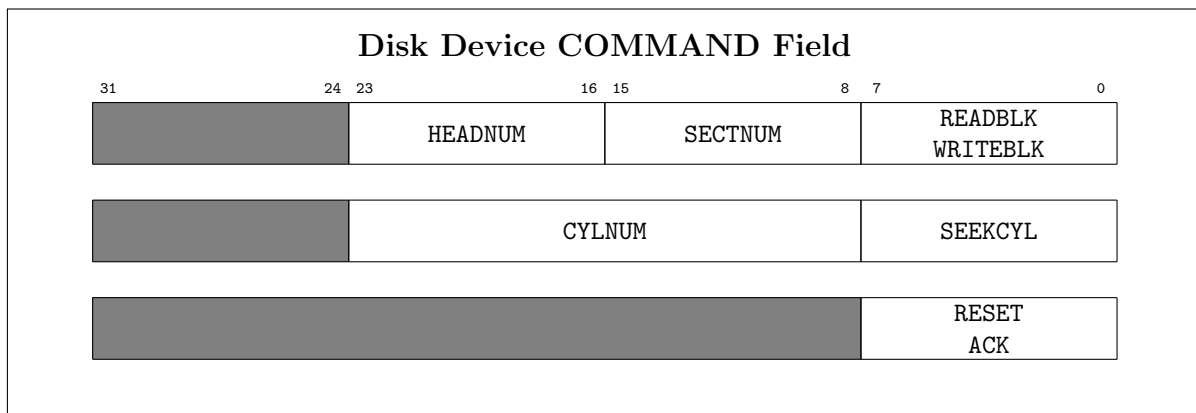

Status codes 1, 2, and 47 are completion codes. An illegal parameter may be an out of bounds value (e.g. a cylinder number outside of  $[0..(MAXCYL-1)]$ ), or a non-existent physical address for DMA transfers.

A disk drives device register **DATA0** field is read/writable and is used to specify the starting physical address for a read or write DMA operation. Since memory is addressed from low addresses to high, this address is the lowest word-aligned physical address of the 4KB block about to be transferred.

A disk drives device register **COMMAND** field is read/writable and is used to issue commands to the disk drive.

Code	Command	Operation
0	RESET	Reset the device and move the boom to cylinder 0
1	ACK	Acknowledge a pending interrupt
2	SEEKCYL	Seek to the specified <i>CYLNUM</i>
3	READBLK	Read the block located at ( <i>HEADNUM</i> , <i>SECTNUM</i> ) in the current cylinder and copy it into RAM starting at the address in <b>DATA0</b>
4	WRITEBLK	Copy the 4KB of RAM starting at the address in <b>DATA0</b> into the block located at ( <i>HEADNUM</i> , <i>SECTNUM</i> ) in the current cylinder

The format of the **COMMAND** field, as illustrated in Figure 5.4, differs depending on which command is to be issued:

A disk operation is started by loading the appropriate value into the **COMMAND** field. For the duration of the operation the devices status is Device Busy. Upon completion of the operation an interrupt is raised and an appropriate status code is set; Device Ready for successful completion or one of the error codes. The interrupt is then acknowledged by issuing an ACK or RESET command.

Disk device performance, because both read and write operations are DMA-based, strongly depends on the system clock speed. While read/write throughput may reach MBs/sec in magnitude, the disk hardware operations remain in the millisecond range.

## 5.4 Tape Devices

MPS2 supports up to eight tape-removable, DMA supporting, read-only tape devices. All MPS2 tape devices support a blocksize of 4KB. Each installed tape devices register **DATA1** field is read-only and describes the current marker under the tape head when the device is idle.

Code	Marker	Meaning
0	<u>EOT</u>	End of Tape
1	<u>EOF</u>	End of File
2	<u>EOB</u>	End of Block
3	<u>TS</u>	Tape Start

A tape starts with a TS marker and ends with an EOT marker. It may be viewed as a collection of blocks, delimited by EOB markers, which are divided into files, delimited by EOF markers. An EOF marker acts as the EOB marker for the last block of the file and the EOT marker act as the EOF (and therefore also an EOB) marker for the last file on the tape.

When there is no tape cartridge loaded into the tape device, the **DATA1** field will contain the EOT marker, and the **STATUS** field will contain the Device Ready code. Since there is no tape cartridge present, the **COMMAND** field, though, will not accept any commands. Only when a tape is loaded does the device wake up and begin accepting commands. When a tape cartridge is loaded, the tape device rewinds the cartridge back to the TS marker.

A tape drives device register **STATUS** field is read-only and will contain one of the following status codes:

Code	Status	Possible Reason for Code
0	Device Not Installed	Device not installed
1	Device Ready	Device waiting for a command
2	Illegal Operation Code Error	Device presented unknown command
3	Device Busy	Device executing a command
4	Skip Error	Illegal command/hardware failure
5	Read Error	Illegal command/hardware failure
6	Back 1 Block Error	Illegal command/hardware failure
7	DMA Transfer Error	Illegal physical address/hardware failure

Status codes 1, 2, and 47 are completion codes. An illegal parameter may be an attempt to read beyond the EOT marker or a non-existent physical address for DMA transfers.

A tape drives device register **DATA0** field is read/writable and is used to specify the starting physical address for a DMA read operation. Since memory is addressed from

low addresses to high, this address is the lowest word-aligned physical address of the 4 KB block about to be transferred.

A tape drives device register **COMMAND** field is read/writable and is used to issue commands to the tape drive.

Code	Command	Operation
0	RESET	Reset the device and rewind the tape to <u>TS</u> marker
1	ACK	Acknowledge a pending interrupt
2	SKIPBLK	Forward the tape up to the next <u>EOB/EOT</u>
3	READBLK	Read the current block up to the next <u>EOB/EOT</u> marker and copy it into RAM starting at the address in <b>DATA0</b>
4	BACKBLK	Rewind the tape to the previous <u>EOB/EOT</u> marker

A tape operation is started by loading the appropriate value into the **COMMAND** field. For the duration of the operation the devices status is Device Busy. Upon completion of the operation an interrupt is raised and an appropriate status code is set; Device Ready for successful completion or one of the error codes. The interrupt is then acknowledged by issuing an ACK or RESET command.

Tape device performance, because read operations are DMA-based, strongly depends on the system clock speed. Tape read throughput can range from 2 MB/sec when the processor clock is set at 1 MHz, to over 4 MB/sec when the processor clock is bumped up to 99 MHz.

## 5.5 Network (Ethernet) Adapters

MPS2 supports up to eight DMA supporting network (i.e. Ethernet) adapters. Though these devices are DMA-based, they are not block devices. Network adapters operate at the byte level and transfer into/out of memory only the amount of data called for. Since packets on a network typically follow standard MTU sizes, this data should never exceed (by much) 1500 bytes.

Network adapters share some characteristics with terminal devices; they are simultaneously both an input device and an output device. As an output device, network adapters behave like other peripherals: a write command is issued and when the write (i.e. transmit) is completed, an interrupt is generated.

For packet receipt, there are two modes of operation:

- Interrupt Enabled: Whenever a packet arrives, an interrupt is generated - this interrupt is not the result of an earlier command. After ACKing this interrupt one issues a READNET command to read the packet. When the read is completed, another interrupt is generated, which itself must also be ACKed. In Interrupt

Enabled mode, each incoming packet, when successfully read, is a two-interrupt sequence.

- **Interrupt Disabled:** When packets arrive, no interrupt is generated. The network adapter must be polled to determine if a packet is available. The READNET command is non-blocking, and returns 0 if there is no packet to be read. The READNET command will still generate an interrupt, which must be ACKed, upon its conclusion.

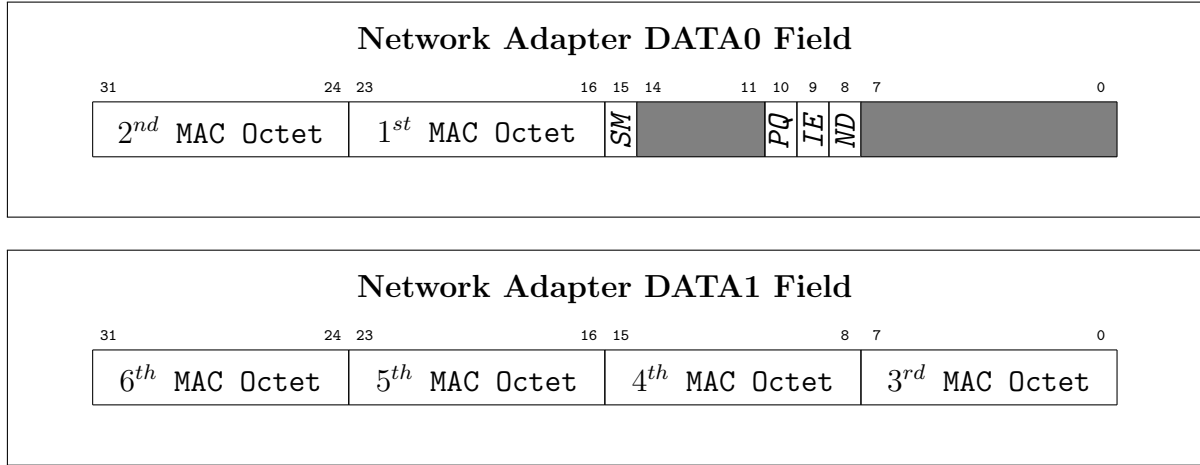

A network adapters device register **STATUS** field is read-only and will contain one of the following status codes:

Code	Status	Possible Reason for Code
0	Device Not Installed	Device not installed
1	Device Ready	Device waiting for a command
2	Illegal Operation Code Error	Device presented unknown command
3	Device Busy	Device executing a command
5	Read Error	Error reading packet from device
6	Write Error	Error attempt to send packet
7	DMA Transfer Error	Illegal physical address/hardware failure
128	Read Pending	Interrupts Enabled and packet present

Status codes 1, 2, and 57 are completion codes. An illegal address may be an out of bounds value or a non-existent physical address for DMA transfers.

Status code 128 is not a distinct status code, it is used in a logical OR fashion with the other status codes. Hence there are actually thirteen status values: 0, (1 & 129), (2 & 130), . . . , (7 & 135). For example, a status code value of 130 indicates that both an illegal operation was requested AND there is a packet pending for reading. The Read Pending status codes are only used when the network adapter is operating Interrupt Enable mode.

Code	Command	Operation
0	RESET	Reset the device and reset all configuration data to defaults
1	ACK	Acknowledge a pending interrupt
2	READCONF	Read configuration data into DATA0 & DATA1
3	READNET	Read the next packet from the adapter and copy it into RAM starting at the address in DATA0
4	WRITENET	Send a packet of data starting at the RAM address in DATA0, whose length is in DATA1
5	CONFIG	Update adapter configuration data from values in DATA0 & DATA1

The **DATA0** fields, during configuration operations (READCONF & CONFIG), are defined as follows:

- *ND* (NAMED, bit 8): When **DATA0.ND**=1, the network adapter will automatically fill all outgoing packets source MAC address field with the network adapters MAC address.
- *IE* (Interrupt Enable, bit 9): If **DATA0.IE**=1, whenever a packet is pending on the device (i.e. waiting to be read), it will immediately generate an interrupt. After ACKing this interrupt, one issues a READNET command to facilitate the reading of the packet. The READNET command must then also be ACKed.
- *PQ* (PROMISQ, bit 10): If **DATA0.PQ**=1 the network adapter will capture and save all packets its receives. When **DATA0.PQ**=0, the device will ignore/drop any packets not intended for its MAC address. Broadcast packets will still be received even when **DATA0.PQ**=0.
- *SM* (SetMAC, bit 15): When **DATA0.SM**=1 and a CONFIG command is issued, the MAC address of the adapter is updated to the values in **DATA0** & **DATA1**. When **DATA0.SM**=0 and a CONFIG command is issued, the adapters MAC address remains unchanged.

As described above, the **DATA0** & **DATA1** fields are overloaded; either containing device status values or DMA addresses and lengths. One uses the CONFIG to set network adapter configuration values. Similarly, after a READNET or WRITENET operation, one can use a READCONF operation to reset the **DATA0** & **DATA1** registers to reflect the current adapter configuration values.

## 5.6 Printer Devices

MPS2 supports up to eight parallel printer interfaces, each one with a single 8-bit character transmission capability.

The **DATA0** field for printer devices is read/writable and is used to set the character to be transmitted to the printer. The character is placed in the low-order byte of the **DATA0** field. The **DATA1** field, for printer devices is not used.

A printers device register **STATUS** field is read-only and will contain one of the following status codes:

Code	Status	Possible Reason for Code
0	Device Not Installed	Device not installed
1	Device Ready	Device waiting for a command
2	Illegal Operation Code Error	Device presented unknown command
3	Device Busy	Device executing a command
4	Print Error	Error during character transmission

Status codes 1, 2, and 4 are completion codes.

A printers device register **COMMAND** field is read/writable and is used to issue commands to the printer interface.

Code	Command	Operation
0	RESET	Reset the device interface
1	ACK	Acknowledge a pending interrupt
2	PRINTCHR	Transmit the character in DATA0 over the line

A printer operation is started by loading the appropriate value into the **COMMAND** field. For the duration of the operation the devices status is Device Busy. Upon completion of the operation an interrupt is raised and an appropriate status code is set; Device Ready for successful completion or one of the error codes. The interrupt is then acknowledged by issuing an ACK or RESET command.

The printer interfaces maximum throughput is 125 KB/sec.

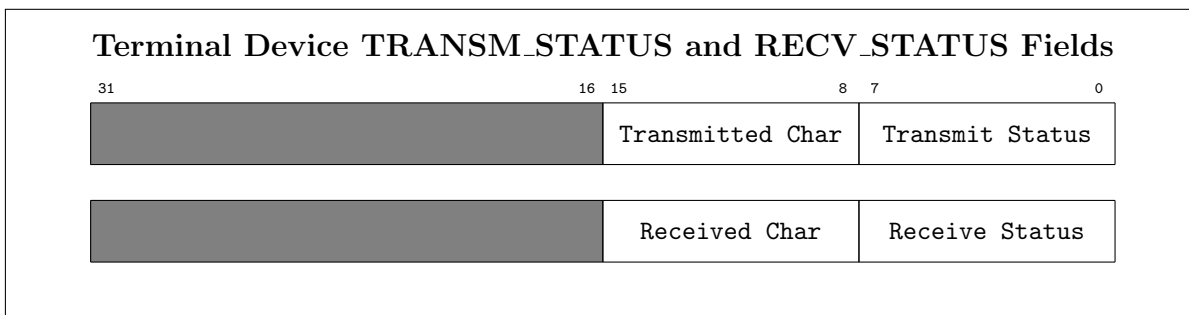

## 5.7 Terminal Devices

MPS2 supports up to eight serial terminal device interfaces, each one with a single 8-bit character transmission and receipt capability.

Each terminal interface contains two sub-devices; a transmitter and a receiver. These two sub-devices operate independently and concurrently. To support the two-subdevices a terminal interfaces device register is redefined as follows:

Field #	Address	Field Name
0	(base) + 0x0	RECV STATUS
1	(base) + 0x4	RECV COMMAND
2	(base) + 0x8	TRANSM STATUS
3	(base) + 0xc	TRANSM COMMAND

The **TRANSM\_STATUS** and **RECV\_STATUS** fields (device register fields 0 & 2) are read-only and have the following format.

The *Status* byte has the following meaning:

Code	RECV STATUS	TRANSM STATUS
0	Device Not Installed	Device not installed
1	Device Ready	Device Ready
2	Illegal Operation Code Error	Illegal Operation Code Error
3	Device Busy	Device Busy
4	Receive Error	Transmission Error
5	Character Received	Character Transmitted

The meaning of status codes 04 are the same as with other device types. Furthermore:

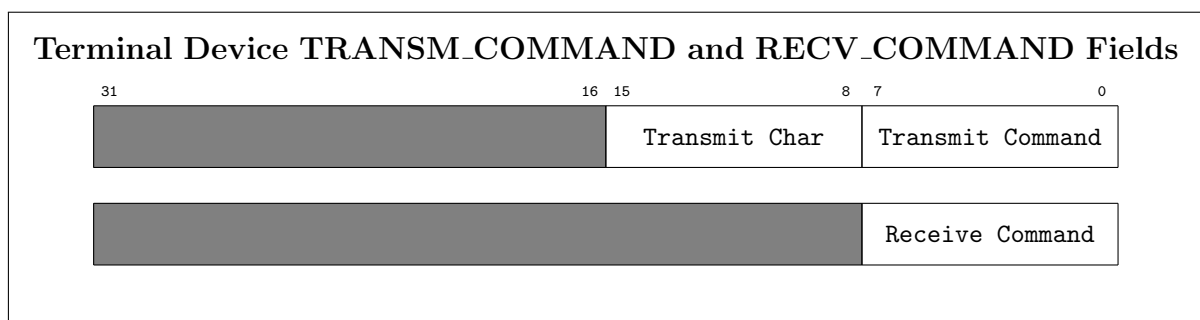

- The Character Received code (5) is set when a character is correctly received from the terminal and is placed in **RECV\_STATUS.RECVD-CHAR**.
- The Character Transmitted code (5) is set when a character is correctly transmitted to the terminal and is placed in **TRANSM\_STATUS.TRANS-CHAR**.

- The Device Ready code (1) is set as a response to an ACK or RESET command.

A terminals **TRANSM\_COMMAND** and **RECV\_COMMAND** fields are read/writable and are used to issue commands to the terminals interface.

Code	TRANSM COMMAND	RECV COMMAND	Operation
0	RESET	RESET	Reset the transmitter or receiver interface
1	ACK	ACK	Ack a pending interrupt
2	TRANSMITCHAR	RECEIVECHAR	Transmit or Receive the character over the line

The **TRANSM\_COMMAND** and **RECV\_COMMAND** fields have the following format:

**RECV\_COMMAND.RECV-CMD** is simply the command.

The **TRANSM\_COMMAND** field has two parts; the command itself (**TRANSM\_COMMAND.TRANSM-CMD**) and the character to be transmitted (**TRANSM\_COMMAND.TRANSM-CHAR**).

A character is received, and placed in **RECV\_STATUS.RECVD-CHAR** only after a **RECEIVECHAR** command has been issued to the receiver.

The operation of a terminal device is more complicated than other devices because it is two sub-devices sharing the same device register interface. When a terminal device generates an interrupt, the (operating systems) terminal device interrupt handler, after determining which terminal generated the interrupt, must furthermore determine if the interrupt is for receiving a character, for transmitting a character, or both; i.e. two interrupts pending simultaneously.

If there are two interrupts pending simultaneously, both must be acknowledged in order to have the appropriate interrupt pending bit in the Interrupt Line 7 Interrupting Devices Bit Map turned off.

To make it possible to determine which sub-device has a pending interrupt there are two sub-device ready conditions; Device Ready and Character Received/Transmitted.

While other device types can use a Device Ready code to signal a successful completion, this is insufficient for terminal devices. For terminal devices it is necessary to distinguish between a state of successful completion though the interrupt is not yet acknowledged, Character Received/Transmitted, and a command whose completion has been acknowledged, Device Ready.

A terminal operation is started by loading the appropriate value(s) into the **TRANSM\_COMMAND** or **RECV\_COMMAND** field. For the duration of the operation the sub-devices status is Device Busy. Upon completion of the operation an interrupt is raised and an appropriate status code is set in **TRANSM\_STATUS** or **RECV\_STATUS** respectively; Character Transmitted/Received for successful completion or one of the error codes. The interrupt is acknowledged by issuing an ACK or RESET command to which the sub-device responds by setting the Device Ready code in the respective status field.

The terminal interfaces maximum throughput is 12.5 KB/sec for both character transmission and receipt.

# Chapter 6

## BIOS & System Library

### 6.1 BIOS

#### 6.1.1 Bootstrap Function

The bootstrap program bundled with  $\mu$ ARM installation has initializes hardware facilities and starts execution.

The operation it performs are:

1. populate Exception Vector with Branch instructions to basic exception handling routines
2. set default Exception States Vector entries with **Branch to PANIC** instructions
3. retrieve entry point from kernel binary file
4. set execution mode to System mode with ARM ISA and all interrupts enabled
5. set exit point and ramtop value
6. clear all used scratch registers
7. jump to entry point

#### 6.1.2 Low Level Handlers

In addition to bootstrapping the machine, BIOS code provides low level exception handlers:

## Undefined Instruction Exception Handler

When an Undefined Instruction Exception is raised, the processor stores its internal state at the moment of the exception into the *Old Area* of the exception states vector relative to Undefined Exceptions and loads the content of the *New Area*.

## Interrupts Exception Handlers

For both Fast and regular Interrupt Exceptions the processor behaves in a way similar to Undefined Exceptions, it stores its state at the time of the interrupt and loads the *New Area* from Interrupts Exception States Vector's slot.

## Software Interrupt Handler

In addition to the regular operations (the same as the Undef and Interrupts handlers), in case of an SWI instruction the BIOS responds for known Low Level Services and sets the Cause register to the right value for the requested interruption (Syscall or Breakpoint).

## Data and Prefetch Exception Handlers

These two handlers share most of their code and perform special operations in case Virtual Memory is turned on:

- if VM is disabled, Abort Exceptions are treated as Undefined Exceptions,
- else low level TLB management is required.

In the latter case, the handler corrects the return address, setting it to the address of the faulting instruction and stores the processor state in the *TLB Old Area* of the Exception States Vector. It then checks if the Abort was labeled as a TLB-Miss and, if it was the case, it performs the TLB Refill procedure described in Virtual Memory section.

### 6.1.3 Low Level Services

Low level services are requested by issuing a SWI instruction with the right parameter:

#### Halt

By executing SWI #1, the BIOS will print "SYSTEM HALTED." on Terminal 0 and shut down the virtual machine.

## **Panic**

By executing **SWI #2**, the BIOS will print "KERNEL PANIC." on Terminal 0 and enter an infinite loop.

## **LDST**

A **SWI #3** instruction will begin the loading of the processor state stored at the address specified by *a1* register to actual processor's registers, checking destination mode and setting only the right processor's registers window.

## **Wait**

By executing **SWI #4**, the BIOS will put the machine in IDLE state waiting for an interrupt to wake the system up.

## **System Calls / Breakpoints**

If a **SWI #8** or **SWI #9** instruction is executed, the syscall handler passes up the call, setting the right cause in CP15 Cause register.

# **6.2 System Library**

System library is provided by *libuarm*, it offers a small but increasing set of methods to access low level functionalities.

## **tprint(char \*s)**

Print a '\0' terminated array of chars to Terminal 0.

This function uses busy waiting to wait for the device to be ready.

## **HALT()**

Run BIOS Halt function.

## **PANIC()**

Run BIOS Panic function.

## **WAIT()**

Run BIOS Wait function.

**LDST(void \*addr)**

Calls the BIOS function that loads the entire processor state from state\_t stored at *addr* address.

**STST(void \*addr)**

Stores the actual processor state in state\_t structure pointed by *addr*.

**SYSCALL(unsigned int sysNum, unsigned int arg1, unsigned int arg2, unsigned int arg3)**

Generates a software exception leading to kernel defined Syscall handler.

**BREAK(unsigned int arg0, unsigned int arg1, unsigned int arg2, unsigned int arg3)**

Generates a software exception leading to kernel defined Breakpoint handler.

**getSTATUS() / setSTATUS()**

Manipulate Current Program Status Register.

**getCAUSE() / setCAUSE()**

Manipulate Exception/Interrupt Cause register.

**getTIMER() / setTIMER()**

Manipulate Interval Timer.

**getTODHI() / getTODLO()**

Returns the upper/lower part of Time of Day 64-bit register.

**getCONTROL() / setCONTROL()**

Manipulate System Control Register.

**getTLB\_Index() / setTLB\_Index(unsigned int index)**

Manipulate TLB Index register.

### **getTLB\_Random()**

Returns TLB Random register.

### **getEntryHi() / setEntryHi(unsigned int hi) / getEntryLo() / setEntryLo(unsigned int lo)**

Manipulate TLB Entry Hi and Entry Low registers.

### **getBadVAddr()**

Returns BadVAddr register, which contains the faulting address in case of Page Fault Exceptions.

### **TLBWR()**

Write the contents of EntryHi and EntryLo to the TLB slot indicated by TLB Random register value.

### **TLBWI()**

Write the contents of EntryHi and EntryLo to the TLB slot indicated by TLB Index register value.

### **TLBR()**

Read the contents of TLB slot indicated by TLB Index register value in EntryHi and EntryLo registers.

### **TLBP()**

Scan the TLB searching for a pair that matches VPN in EntryHi and ASID in EntryHi or that has G flag set in EntryLo and is Valid, if a match is found, its index in the TLB cache is stored as TLB Index register value, otherwise that register will have 31st bit set to 1.

### **TLBCLR()**

Set all TLB contents to 0.

## Notes

### 8.1 Compilers and compiling

#### 8.1.1 Compilers

To compile a program to be run in  $\mu$ ARM you need an ARM compiler in order to generate code that the CPU is able to understand.

If you happen to be running a machine which is not ARM-based, you will need a cross-compiler (or better a cross-toolchain).

`arm-linux-gnueabi` and `arm-none-eabi` are the cross-toolchains with which the program is tested so they are likely the most compatible, but any toolchain able to compile code for ARM7TDMI processor will work.

#### 8.1.2 Compiling

When it comes the time to actually compile your code, be aware that you need to manually compile and then link each executable, because if `gcc` does all the work, it will include Linux system libraries as well. These libraries will try to "prepare" your program to be executed under Linux OS, adding initializing functions that will "break" execution in a bare metal system like  $\mu$ ARM.

So remember to add `-c` option while compiling each source file as well as `-mcpu=arm7tdmi` to ensure maximum compatibility with the system.

When you have all the required object files, you have to link them together with the following command:

```
arm-some-abi-gcc -nostartfiles -T \\
/usr/include/uarm/ldscripts/elf32ltsarm.h.uarmcore.x \\
/usr/include/uarm/crtso.o1
```

---

<sup>1</sup>optionally you may want to add `/usr/include/uarm/libuarm.o` if you included system library in your code, you can also use `elf32ltsarm.h.uarmaout.x` script to link user mode programs.

The last tool needed for preparing code for execution is `elf2uarm`, it converts elf binary files into  $\mu$ ARM elf files. The tool has three operating modes and two options:

- `-k` : create kernel core file (extension `*.core.uarm`) with symbol table map (extension `*.uarm.stab`)
- `-b` : create bootstrap BIOS file (extension `*.rom.uarm`)
- `-a` : create a.out user program file (extension `*.aout.uarm`)
- `-m` : force creation of symbol table map
- `-v` : verbose mode

## 8.2 Binary Formats

The `elf2uarm` tool is capable of generating three binary file types: `.rom.uarm`, `.core.uarm` and `.aout.uarm`. Each type has a specific purpose and structure.

### 8.2.1 `.rom.uarm`

The `.rom.uarm` binary format is the file format intended for the code to be loaded into system ROM (i.e. the BIOS code). This format is pretty simple, it is composed of a two field wide header followed by the `.text` section.

The header has the following format:

- 0 ROM Header TAG
- 1 `.text` section size in words

### 8.2.2 `.core.uarm` and `.aout.uarm`

Binary file formats used for kernel and user program files (respectively `.core.uarm` and `.aout.uarm`) are essentially based on ELF standard. They have the same structure:

- header section (16 header fields described below)
- `.text` section
- optional `.data` section

Header has the following format:

0	AOUT_HE_TAG:	Header TAG (aout.h defines different executable files magic numbers)
1	AOUT_HE_ENTRY:	Program Entry Point
2	AOUT_HE_TEXT_VADDR:	.text section beginning virtual address
3	AOUT_HE_TEXT_MEMSZ:	.text section actual Byte size
4	AOUT_HE_TEXT_OFFSET:	.text section offset from Header section end
5	AOUT_HE_TEXT_FILESZ:	.text section size (rounded to the next 4KB block)
6	AOUT_HE_DATA_VADDR:	.data section beginning virtual address
7	AOUT_HE_DATA_MEMSZ:	.data section actual Byte size
8	AOUT_HE_DATA_OFFSET:	.data section offset from Header section end
9	AOUT_HE_DATA_FILESZ:	.data section size (rounded to the next 4KB block)

the last 6 header fields are unused.

## 8.3 Hints

When writing Exception Handlers code, it is well advised to pay attention to the Program Counter value stored in the Old Area. As described in Exception Handling section, each exception leave a different value in Link Return register and this value is automatically moved to **Old Area.pc** from low level exception handlers, so, for example, when handling an interrupt, the **Old Area.pc** has to be decreased by 4 to point to the right return instruction.

You may also want look closely to the Low Level Handlers section to better understand what actions are performed by the BIOS code.

## 8.4 Known bugs

- If Symbol Table file is changed during execution the machine can misbehave
